GEOGRAPHIC INFORMATION SYSTEMS

GEOGRAPHIC INFORMATION SYSTEMS MODULE explains the different techniques of spatial analysis in relation to CORE approaches and demonstrates the use of GIS in land use, land cover analysis and vulnerability assessment.

TRAINING MODULE FOR TRAINERS

CLIMATE CHANGE COMMISSION

The Climate Change Commission, an independent and autonomous body that has the same status as that of a national government agency, is under the Office of the President of the Philippines. It is the lead policy-making body of the government which is tasked to coordinate, monitor, and evaluate programs and action plans of the government relating to climate change pursuant to the provisions of the Republic Act No. 9729 or the Climate Change Act as amended by Republic Act No. 10174 or the People's Survival Fund.

GLOBAL GREEN GROWTH INSTITUTE

The Global Green Growth Institute (GGGI) is a new international organization committed to strong, inclusive green growth. GGGI assists developing and emerging countries with integrating their ambitions for strong economic performance and environmental sustainability with the goal of bringing about poverty reduction, job creation, social inclusion, and climate change mitigation and adaptation. Headquartered in Seoul, GGGI was established by treaty in June 2012 at the United Nations Rio+20 Conference by an initial group of eighteen nations who share the organization's vision. To date, there are a total of 24 Member Countries who joined the organization. GGGI has a diverse portfolio of programs in developing countries around the world. These in-country programs, together with global products and services, focus on delivering results through an integrated approach of evidence based green growth planning and implementation aligned to countries' development priorities. The organization also focuses on knowledge development and management activities which build a strong theoretical and empirical basis for green growth, while providing concrete options and guidance for policymakers; as well as building the conditions for public and private green infrastructure investments.

PREFACE

The Philippines is highly vulnerable to the impacts of climate change. As witnessed through the devastation from typhoons Yolanda (2013), Glenda (2014), and Lando (2015), millions of Filipinos were affected and communities incurred costly damages and forced to rebuild. In anticipation of stronger typhoons hitting the country, climate change adaptation and mitigation is vital to the development and preparedness of Local Government Units (LGUs) and the people they serve.

The methodologies and tools offered in this publication are intended to raise national awareness and competence among national and local government institutions, civil society, private sector, and communities. This publication provides information outlining mechanisms on how to develop capacities of decision makers, local planners and trainers in integrating science-based assessments into policies, plans, and programs to make communities adaptive and resilient to climate risks.

This module is one of the many references that the users may utilize in developing their respective development plans.

The Climate Change Commission (CCC) is grateful to our partner, the Global Green Growth Institute (GGGI) – Philippines for providing the needed technical assistance in the development of this module together with the technical team composed of individuals from the Resources, Environment, and Economics Center for Studies, Inc. (REECS).

Definition of Terms

Hazard – a potentially damaging event or physical disturbance, which can be categorized as natural (i.e., soil erosion, landslides, flood, drought) and man-made (i.e., deforestation/biodiversity loss, forest fire, water pollution).

Geographic Information Systems (GIS) – a computer system for entering, storing, naming, retrieving, transforming, analyzing, and displaying spatial data.

Geospatial technology – a technology that integrates remote sensing and global navigation systems.

Geomatics – a scientific approach to the fundamental issues raised by the use of GIS and related technologies.

Risk – the possibility or likelihood of danger, disaster, harm or loss.

Standardized Precipitation Index – a tool developed primarily for defining and monitoring drought.

Vulnerability – the degree to which a system is susceptible or unable to cope with adverse effects of natural or man-made (anthropogenic) hazards.

Vulnerability Assessment – a profile discussing the relationship between natural and anthropogenic hazards and recipient subject (watershed).

I. Introduction

1.1. Overview of the Module

To help build the country's climate resilience and promote green growth, the Communities for Resilience (CORE) Initiative targets State Universities and Colleges near the 18 major river basins in the country. Similar to the demonstration of the Ecotown Framework in 2014, the trainings aim to reduce the vulnerability of communities and ecosystems to climate change impacts and promote adaptation measures by building their capacities through a scientific approach.

In order to achieve these goals, appropriate data should be gathered and organized to determine the size of the locality, and the adaptation and mitigation activities that must be performed. This is done by utilizing Global Information Systems (GIS) that facilitate assessment and map generation of a given locality. Without this capability, a comprehensive risk and vulnerability assessment, land use zoning, and change modelling are impossible to identify.

This GIS module addresses the GIS users' domain focusing on trainers from the academe and research. The important aspects of GIS will be explained relevant to the CORE Initiative and the 2014 Ecotown Framework.

1.2. Objectives of the Module

By the end of the module, the participants will be able to:

- Demonstrate and guide local government units (LGUs) in utilizing GIS during their respective CORE Capacity Development trainings;
- Appreciate the role of GIS in Ecotown Framework project;
- Explain the different techniques of spatial analysis in relation to CORE approaches; and
- Demonstrate the use of GIS in land use, land cover change analysis, and vulnerability assessment.

1.3. Brief Description

The GIS Module for Trainers covers all the topics relevant to the CORE Initiative and the Ecotown Framework, as this module's target users will be responsible in the roll out for LGU planners. Trainers will learn the evolution of GIS, data structure and spatial analysis, the role of GIS in hazards and disaster risk-reduction, how it is used in land use decision-making and local governance, and how to analyze change and transition analyses.

1.4. Relevance of the Module for Trainers

Section 2 of Republic Act No. 10121 or the Philippine Disaster Risk Reduction and Management Act of 2010 underlines the development, promotion and implementation of a National Disaster Risk Reduction and Management Plan that "aims to strengthen the capacity of the government and the local government units,

together with the partner stakeholders, to build the disaster resilience of communities, and to institutionalize arrangements and measures for reducing disaster risks, including projected climate risks, and enhancing disaster preparedness and response capabilities at all levels. “ To ensure a multi-stakeholder participation, GIS-based maps should be used as policy, planning, and decision-making tools. Therefore, the transfer of right knowledge and application of GIS to LGUs using this module would be a major intervention in identifying, assessing, and managing the hazards that may occur in their localities.

1.5. Summary of Topics

The Module for Trainers covers all the topics in GIS, and the discussions are expected to be informative, substantive, and interactive.

From GIS technology to Geomatics

This section traces the GIS’ operational definition and how the technology evolved into a new field of scientific endeavor that we now call Geomatics.

Data structure and spatial analysis

This section provides a brief discussion on the transformation of paper maps to digital themes with the advent of computers. A comparison is given between analytical cartography and spatial analysis. Discussions on common coordinate systems, datums and projections, data structures and spatial analysis is explored.

GIS, Hazards and Disasters

This part describes a GIS-based mapping and assessment that determines an area’s vulnerability to climate hazards. The assessment is undertaken by determining inherently sensitive areas brought by topography and their exposure. Vulnerability or hazard maps will be prepared to show which areas in a municipality are highly susceptible to the adverse impacts of changing climate.

Of the many different types of hazards related to climate change, 1) flood, 2) drought, and 3) landslides are selected for assessment using the Ecotown approaches. In addition, this section intends to present the different steps in hazard mapping and assessment related to the determination of exposed elements, analysis of population exposed to hazards, and the spatial extent to hazards.

GIS for Land Use Decision-making

One of the objectives of this module is to describe the land capability classification and zoning, which can be used by LGUs in prescribing appropriate management prescriptions and activities. These become necessary when addressing continuously varying quantitative spatial properties, an issue typical to land use planning. The advantage of homogenous land units resulting from land classification procedure allows the land to be allocated in a rational manner. The allocation of land units depends on the capability as well as suitability to a specific land use. Land use zones

are delineated based on land capability. Thus, the output zonation and the indicative land uses are intended to provide a scientific basis for allocating the lands in the municipalities for various uses.

GIS for Local Governance

Local government units are probably the most effective players in mainstreaming the CORE Initiative. LGUs are at the frontline owing to their presence in various activities and developments in the area. In addition, LGUs are the operative entities that can sustain efforts at protecting and restoring forests and natural resources. Compared to other government agencies with similar concerns, LGUs have the 'home advantage.' Thus, having a GIS unit to handle the spatial databank of the organization is desirable. It is important to emphasize that GIS is a tool for better decision-making.

This section describes a community-based GIS, and poverty mapping techniques in developing updated baseline information that can be used as basis for a systematic and organized rehabilitation and development of a certain locality.

Land Change Modelling

This part displays the different time window of land covers that are of interest in the change analyses conducted in the previous cotown projects. These are valuable take-off points in mapping and visualizing existing land cover, as well as transition from other categories. Determining the land use and land cover change provide the basis for formulating corresponding restoration or reforestation interventions in the communities in particular, and the ecosystem in general.

As such, this section shares a menu of viable land change modelling techniques, which LGU planners can consider and use in mapping their localities.

II. Module Content

2.1. What Is GIS all about?

1. Definitions of GIS

In some literature, Geographic Information Systems is basically defined as:

- A collation of data about spatial distribution of significant properties of the earth's surface (Woodridge, 1990).
- A computer system capable of assembling, storing, manipulating, and displaying geographically referenced information (Itami *et al.*, 1993 and Eastman, 1997).
- The management, analysis, and manipulation of spatially referenced information in a problem solving synthesis (Fisher and Lindenberg, 1989).

- An institutional entity, reflecting an organization structure that integrates technology with a data expertise and continuing financial support over time (Carter, 1989).
- A system for handling data which are directly and indirectly spatially referenced to Earth. It may be used for capturing, storing, validating, maintaining, manipulating, analyzing, displaying or managing such data. It is normally considered to involve a spatially referenced computer database and appropriate software. A primary function of a GIS is its ability to integrate data from a variety of sources.
- A tool for legal, administrative and economic decision-making and an aid for planning and development, which consists on the one hand, a database containing spatially referenced land-related data for a defined area, and on the other hand, procedures and techniques for the systematic collection, updating, processing, and distribution of the data. The base of a GIS is a uniform spatial referencing system for the data in the system which also facilitates the linking of data within the system to other land-related data (International Federation of Geographers FIG).

2. From GIS technology to Geomatics

As a technology, GIS is able to store, analyze, and display spatial and non-spatial data. As a decision support system, GIS involves the integration of geographically-referenced data in addressing issues that have to do with resources location and allocation, land change modelling, crop and species suitability, conducting land capability assessment and land use suitability analysis, and modelling of hazard vulnerability, among many others.

GIS has evolved into new applications: as a technology that integrates remote sensing and global navigation systems, it is called geospatial technology. As a new field of science, it is called geomatics – a scientific approach to the fundamental issues raised by the use of GIS and related technologies. In addition, GIS is being integrated into erstwhile problem solving activities not only as a platform for visualization, but also for modeling of impacts, prescribing management interventions and mitigating measures, as well as ensuring the sustainability of the chosen intervention option.

3. Data Structure and Spatial Analysis

a. *Georeferencing*

Georeferencing is the act of assigning locations to point of interest (POIs) on the basis of a coordinate system. The term is synonymous to geocoding or geo-locating. In transforming an analog map (or paper map), georeferencing also refers to map registration. Thus, data that have no location is termed non-spatial, non-loational or spatial.

Some commonly used georeferencing systems are: place name, postal address, postal code, linear referencing system, cadastral system, public land survey system, latitude/longitude, universal transverse Mercator, and state plane coordinates. A place name is the simplest form of georeferencing and most likely developed by the early hunter-gatherers. Using distinctive features of the landscape (*i.e.*, old tree, presence of a

spring or waterfall, bridge crossing), a traveler can find his/her way towards a destination.

For a villager in remote areas, the concept of location is different from a person schooled in surveying. Directions are given using landmarks like a river crossing or a foot bridge, and seldom in terms of the cardinal directions North, East, West or South. In some instances, landmarks have historical attachments and stories that only local residents are familiar. Even distance for a local resident is different – a certain distance is measured by the number of river crossings and hills traversed in order to reach the destination.

b. Data and information

Data may be defined as a body of facts or figures gathered systematically. In their raw form, data are mere numbers representing measurements from field surveys and inventories. However, it needs to be transformed in some way to be useful for decision-making and this transformation has to happen under a controlled situation. At the same time, feedback is necessary to ensure that the desired set of information is established.

c. Data input

Data come from two general sources: primary and secondary. Primary data usually refer to those that have been gathered by an on-going activity or project. These data may be results of field measurements (including sketches) from resource inventories and surveys, or from interviews (*i.e.*, focused group discussions, workshops and meetings). Secondary data already exist in some form and only need to be collected, organized, and encoded into a text editor, spreadsheet, or database following some pre-determined format. Examples of secondary data are reports (monthly accomplishments, quarterly, semi-annual, annual) and compilations, watershed profiles, statistical reports, books and journals, satellite image/photograph, and analog maps.

Data input may be done from satellite imageries, existing maps, tabular data, field survey data, and data from other digital databases.

The process of data input consists of encoding the spatial (*i.e.*, digitizing) and non-spatial data (*i.e.*, digital encoding) and consequently linking these together. Basic encoding can be performed by the following:

- Digitizing of features from analog maps.
- Encoding of coordinates from GPS readings either automatically or manually. Most GPS units enable easy downloading of waypoints to the computer.
- Automatic line following. GIS/Computer aided design (CAD) software can be set to automatically digitize line features just by following the cursor (*i.e.*, stream-mode).
- Some GIS and CAD softwares contain functions that automatically digitize contours from elevation maps.
- Digital image processing of satellite images.

Data acquisition methods may be done through field surveys, digitizing of existing maps and aerial photographs, vectorization of remote sensing images, and existing digital databases.

Field survey methods include conventional position fixing systems like triangulation, traverse surveys and levelling techniques; and satellite-based positioning systems (*i.e.*, GPS). Image processing requires radiometric and geometric corrections, and image enhancement and classification.

Data output from GIS can come in varied forms apart from the usual printed maps. These can be on-screen displays, graphs, tabular reports, and data files (as jpg image, database file or in map format). More importantly, data output should be presented in the most understandable manner and form to end-users.

d. Data quality

Data quality can be categorized into: positional accuracy, attribute accuracy, logical consistency, completeness, and lineage.

Positional accuracy is commonly defined by the user depending on the level of detail that is required by the GIS project. Points derived from GPS measurements depends on the instrument (or quality of the GPS receiver), method of position acquisition, and the quality of the signal. In terms of map sources, positional accuracy is directly related to map accuracy.

Attribute accuracy likewise depends on the instrument used and the survey method. On the other hand, logical consistency has to do with logical organization of the data, while completeness points to the sufficiency of the results derived from the GIS analysis. In other words, depending on the objective of the GIS project, the results of the GIS analysis will reveal gaps in data collected.

e. Basic representations of spatial data

Earth features are encoded into GIS with three fundamental representations: points, lines, and area (or polygons). A point is described by its XY coordinate. In GIS, points, lines or arcs, and areas or polygons are structured such that relationships are established among them. Geometry tells where objects are located, while topology tells how objects are related. In other words, spatial relationships are established indicating adjacency (*i.e.*, A is adjacent to D), connectivity (*i.e.*, 1 connects with 2), and containment (*i.e.*, E is outside the boundary of the area of study). More importantly, with topology, the file size of the GIS theme is considerably reduced.

f. GIS data model

GIS uses two kinds of data: spatial (or locational) and non-spatial (*i.e.*, non-locational or aspatial) data.

Spatial is described by:

- Where is it?
- Points/Lines/Polygons
- X,Y coordinates
- Latitude/Longitude
- Postcode

Non – spatial is described by:

- What is it?
- How much is it? (Quantities)
- What is its condition/status (Qualities)

The vector data model shows features as points, lines, or areas (also polygons) based on their XY coordinates. Thus, a soil sampling pit would be represented by a point represented as a single coordinate pair; a river by a line which is represented by a string of coordinate pairs; and vegetation by an area represented by a string of coordinate pairs whose endpoints converge. These features are considered to be spatial data – which means that they all have a specific location on earth.

The raster approach, on the other hand, has a simple data structure which makes spatial analysis more straightforward. The area of study is subdivided into a mesh of cells (or pixels – picture elements) or grids of pre-determined size. Each cell is assigned a numeric value which may represent a feature identifier, a qualitative, or a quantitative attribute (Eastman, 1997). Normally, only one attribute per raster unit (*i.e.*, square or rectangle) is possible for every layer. And if the raster unit is too large, smaller features are missed and thus remain unmapped. Thus, the quality of the analysis depends on grid size or raster resolution. Rasterization is the conversion of a vector GIS theme into raster format.

g. Spatial analysis

There are six categories of spatial analytical techniques in GIS: 1) topological overlay, 2) proximity analysis, 3) feature extraction, 4) feature merging, 5) join and 6) relate. The last two refer to relational database operations. Topological overlay combines GIS themes in a pairwise manner to form new themes with a new set of attributes and a resultant GIS theme. In vector data model, there are three situations that arise when conducting overlay analysis: point in polygon, line on polygon and polygon on polygon.

Boolean algebra is a useful topological overlay operation that can be implemented in both vector and raster environments. This operation uses Boolean logic and may be applied to all data types: binary, nominal, ordinal, interval, and ratio. It uses the logical operators AND, OR, NOT, and XOR.

Proximity analysis can be visualized by creating a new polygon with a specified distance around a point, line, or area. In raster analysis, the technique is called buffering. The buffer distance need not necessarily be a fixed distance as these distances can be specified in an attribute table.

After executing the buffer operation, overlaps are intersected and dissolved to generate a single polygon. Line buffering is executed at right angles to each line segment comprising the line feature. Similarly, overlaps are intersected and dissolved to generate a single polygon. In buffering a polygon, the same operation is done as line buffering. The resulting polygon is usually outside the original polygon creating an envelopment. It is also possible to invoke the operation to generate a buffer zone from both sides of the polygon perimeter as in line buffering.

Applications of buffering include buffer zones for protected areas; lakes and rivers (*i.e.*, 20 m on both sides to be slated for protection purposes); noise pollution; waste disposal sites; and right of way among others.

h. Spatial Interpolation

Spatial interpolation seeks to generate a complete picture of the area of study by estimating the values of unsampled areas from sampling points. The basic premise in interpolation (including extrapolation) is that points that are closer together in space are more likely to have similar properties than those farther apart (Burrough, 1986). The quality of the result of spatial interpolation is dependent on the mathematical function, degree of certainty on the sampling points, and quality of the output or product.

There are two main groupings of interpolation techniques: deterministic and geostatistical. Deterministic interpolation techniques create surfaces from measured points, based on either the extent of similarity (inverse distance weighted) or the degree of smoothing (radial basis functions). Geostatistical interpolation techniques (kriging) utilize the statistical properties of the measured points. Geostatistical techniques quantify the spatial autocorrelation among measured points, and account for the spatial configuration of the sample points around the prediction location.

2.2. Importance of GIS in the CORE Framework

GIS is designed as a generic system for handling any kind of spatial data. This technology can be used for scientific investigations, resources management, environmental monitoring and modelling, habitat assessment, vulnerability assessment, decision support systems, development planning, urban planning, and mapping among others.

Similarly, GIS provides techniques of investigation and knowledge of the watershed characteristic values, and to generate land use zones based on topography, land use and precipitation factors. It can apply in land use planning to classify a whole watershed area, which is heterogeneous in nature, into different homogeneous groups through the land capability classification technique. It can also be used to develop a model for land-use optimization in the watershed, investigate the effects of slope information on soil erosion estimates, and identify areas at risk of visual degradation.

For instance, GIS might allow planners to easily calculate emergency response times in the event of a natural disaster, or be used to find areas that need protection and rehabilitation.

In particular, GIS technology is often used in climate change vulnerability and impact assessment. GIS-assisted integration with climatic and biophysical information in other communities (*i.e.*, barangay, municipality, and region) is possible. Mapping can be done through the use of computer with GIS. Hence, training on use of GIS is necessary.

2.3. Application of GIS

1. GIS, Hazards and Disasters

Hazard assessments can be conducted based on different factors and their relative weights. Vulnerability maps to climate hazards for a climate scenario based on future with time periods of 2020 (base year 2006-2035) and 2050 (base year 2036-2065) can be developed following the processes as illustrated below (Figure 1).

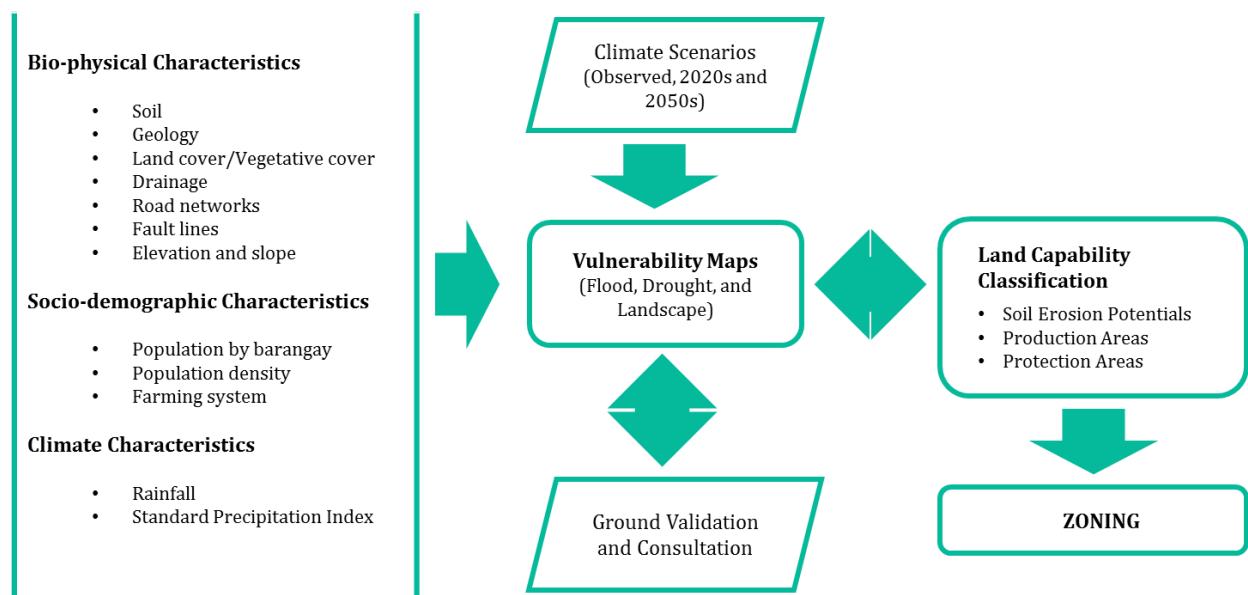

Figure 1. Vulnerability assessment structure for flood, drought and rain-induced landslide (CFSHD-DAP, 2015; USAID-DENR, 2015)

a. Baseline climate and climate scenario

The climate datasets, climate scenarios and projections of future changes in temperature and rainfall in 2020 and 2050 prepared by the Philippine Atmospheric, Geophysical and Astronomical Administration (PAGASA) can be used to assess future vulnerabilities of a certain locality. The medium-range scenario is within a planning horizon of up to 2050. Outputs of the model under the A1B and A2 scenarios will only diverge after 2050 due to the long lifetimes of greenhouse gases. The outputs of the model runs for the observed months and changes in the monthly rainfall both in 2020 and 2050 can be used in vulnerability assessments in all sectors.

b. Concept of ranking and ratings

Ranking and rating is a technique that provides a mathematical method to analyze and construct a map from overlays or data from other related maps. Each parameter is given a rating, which represents the relative weight of these parameters. The ranking assessment method can be incorporated into GIS-based, multi-criteria decision analysis. There are several ways to deal with the uncertainty about the relative weight of rankings. Assigning ranking to parameters by direct *i.e.*, arbitrary means is likely to induce subjectivity in their rankings, which must be removed in order to eliminate bias in assigning rankings. Among the popular procedures for assigning ranking is the pair-wise comparison method, which is based on the statistical/heuristics approach. Its advantage is that only two criteria have to be considered at a time. It is easy to use, as it has high trustworthiness, effectiveness, and quite precise. Ranking is assigned to each parameter that reflects its importance in the event of occurrence, together with the rating for the individual classes that denotes the event intensity. Ranking of each parameter is computed using pair-wise comparison matrix.

Pairwise comparison files can be made in spreadsheet or Microsoft access format. The first line contains the number of factors being compared, then each factor name follows, one per line, in the order they appear in the matrix. The lower left portion of the pairwise comparison matrix is then entered, with one or more spaces separating each cell entry on a line. Fractions or decimals may be entered (*i.e.*, entering 1/2 is the same as entering 0.5).

Details of various parameters and weights are presented in Figure 2. The weights assigned to reflect importance of each parameter are shown together with the rating for individual classes (5 being the highest and 1 the lowest drought influence). The severity of an area depends on the cumulative effects of individual classes. The identification of risk areas requires the factors considered to be combined in accordance with their relative importance. This can be achieved by developing a rating scheme in which the factors and their classes are assigned numerical values. A rating scheme may be developed based on the associated parameters triggering drought, field observations, previous experience and knowledge to the localities.

A typical pairwise comparison of factors

	SPI	Elevation	River/ Spring	Soil	Vegetation	Population Density
SPI	1					
Elevation		2				
River/Spring			3			
Soil				4		
Vegetation					5	
Population Density						6
Total						

Standardized ratings

	SPI	Elevation	River/ Spring	Soil	Vegetation	Population Density	Average
SPI							
Elevation							
River/Spring							
Soil							
Vegetation							
Population Density							
Total	1.0	1.0	1.0	1.0	1.0	1.0	1.0

Figure 2. A pairwise comparison matrix

c. *Hazards assessment*

A GIS-based mapping and assessment can be conducted to determine the area's vulnerability to climate hazards. The assessment can be undertaken by determining inherently sensitive areas due to topography and its exposure. Vulnerability or hazard maps are prepared to show which areas in the watershed or even municipality require immediate attention to minimize the adverse impacts of changing climate. Projected hazard maps may be simulated using overlay analyses associated with different variables based on the observed and projected climate scenarios. Of the many different types of hazards related to climate change, 1) flood, 2) drought, and 3) landslides are selected for assessment in the Eco-town project initiatives. The selection is founded on the understanding that the projected climatic changes in the area involve significant variations in the amount, and seasonal pattern of rainfall. With shorter/drier dry seasons and longer/wetter wet seasons expected to become more prevalent, more frequent flood and drought events are expected to affect the activities of local communities.

i. Rain-induced landslide

Landslide is essentially described as the downward movement of a relatively dry mass of earth and rock. It is a process where soil particles are detached, transported and deposited from one place to another. It is usually triggered by excessive rainfall or the occurrence of an earthquake strong enough to cause instability in the underlying rock layer. The rain-induced landslide hazard maps are assessed and generated based on physical conditions, vegetated factors, and climate change influences given the Global Climate Model (GCM) and scenarios.

The vulnerability to landslide is a function of different physical factors, and the different thematic maps (slope, soil, geology [geo-hazard], land cover, and climate). Essentially, each factor is assigned a relative weight according to its influence in landslide occurrence. Each factor, with the specific hazard values, can be prepared and analyzed for simulation. All physical factors follow the same scaling factor procedures. Degrees within each factor is given relative weights (from low to high) depending on the degree by which these could influence landslide vulnerability. The different factors are described below:

Layer/ Factor	Classes/Ranges	Relative weights
SENSITIVITY		
Elevation (ranges in meters above sea level)	<200	1
	200 – 400	2
	400 – 600	3
	600 – 800	4
	>800	5
Slope (% ranges)	<8	1
	8 – 18	2

	18 – 30	3
	30 – 50	4
	>50	5
Rainfall (buffer ranges in mm)	<100	1
	100 – 200	2
	200 – 300	3
	300 – 500	4
	>500 mm	5
	Tropaquepts w/ Entropepts; Udorthents & Tropepts	1
Soil Morphology (categories)	Tropopsammets w/ Troporthents; Eutrandepts w/ Eutropepts	2
	Tropudalfs w/ Tropepts	3
	Entropepts w/ Dystropepts	4
	Tropudults w/ Tropudalfs; Mountain soils w/ Entisols, Inceptisols, Ultisols and Alfisols	5
	Closed forest; Mangrove forest	1

Annual forest loss (ha/yr)	Loss >10	5
	Loss 5 - 10	4
	Loss 1 – 5	3
	Gain 0 – 5	2
	Gain >5	1
Extent of cultivated areas within the forestlands (in %)	>50	5
	40 – 50	4
	30 – 40	3
	20 – 30	2
	<20	1
ADAPTIVE CAPACITY		
Extent of soil conservation practices in upland areas	Available	1
	Partially available	3
	Not available	5
Reforestation efforts (in %)	>30	1
	20 - 30	2
	10 - 20	3
	<10	4
	None	5

The vulnerability can be described in three (3) categories: low, medium, and high. Areas that are assessed prone to geologic hazards have high exposure to impact of extreme climate variability. This can primarily be associated with the fluctuating pattern and trend of monthly rainfalls.

ii. Flood

Flood is commonly defined as an overflow of water onto normally dry land. It is also described as the inundation of a normally dry area caused by rising water in existing river networks and waterways. In flood assessment, scenarios can be generated given physical factors, vegetative conditions and rainfall amounts based on the GCM with a scenario during the 2020s and 2050s periods.

The susceptibility flood hazard map can be generated based on different factors and their relative weights. The flood modelling is based on the overlay of contributing factors namely slope, land cover/land use, soils, elevation, sub-watershed shape, and stream buffer. Each factor is classified into five (5) categories ranging from very low to very high classes. The different factors are described below:

Layer/ Factor	Classes/Ranges	Relative weights
SENSITIVITY		
Elevation (ranges in m asl)	>150	1
	80 – 150	2
	40 – 80	3
	20 – 40	4
	<20	5
Slope (% ranges)	>30	1
	18 - 30	2
	8 - 18	3
	3 – 8	4
	0 – 3	5
Soil Series	Fine sand	1
	Sandy loam; Fine sandy loam	2
	Loam; Sandy clay loam; Sandy clay; Silty clay; Silt loam	3
	Silty clay loam; Clay loam	4
	Clay	5
Land cover (categories)	Closed forest	1
	Open forest; Plantation	2
	Shrubs; Natural grassland	3
	Agricultural/Cultivated; Pasture land; Built-up	4

	Bare; Water bodies; Inland water; Mangrove forest	5
	<1500	1
	1500 - 2000	2
	2000 - 2500	3
	2500 - 3000	4
	>3000	5
EXPOSURE		
Rainfall (Annual, mm)	<100	5
	100 – 200	4
	200 – 300	3
	300 – 500	2
	>500	1
Proximity to streams and rivers (buffer ranges in m)	<0.25 (almost elongated)	1
	0.25 – 0.40	2
	0.40 – 0.60	3
	0.60 – 0.80	4
	>0.80 (almost circular)	5
Watershed shape (ratio; descriptive)	None	1
	Once	2
	2x	3
	3x	4
	>4x	5
ADAPTIVE CAPACITY		
Frequency of flooding	Fully updated	1
	Partially updated	3
	Not updated	5
Updated maps of flood prone areas	Available	1
	Partially available	3
	Not available	5
Availability of annual historical flood data	Accessible	1
	Partially accessible	3
	Not accessible	5
Access to flood forecasting information	Warning system operational and evacuation routes identified	1
	Warning system operational and evacuation routes partially identified	2
	Warning system not fully operational	3
Warning system and evacuation routes	Warning system not operational	4
	None	5

Based on the overlay analyses of these factors, a flood vulnerability map can be generated given the following equation:

$$\text{Vulnerability} = \frac{\text{Sensitivity} \times \text{Exposure}}{\text{Adaptive Capacity}}$$

Assigned or standard colors represent specific categories and translated into susceptibilities. In short, it is the possibility of floods covered by each colored representation. However, susceptibility flooding, at any, cannot be equated with floodwaters. In particular, the blue color suggests that the areas covered are highly susceptible to flooding at any given event. Although it can be categorized in one single category, this does not mean that the entire town will be flooded all at the same time at any given event, but rather depending on the magnitude of rainfall and influence of associated factors. In any given tropical storms and extreme rainfall events, some parts will be highly affected, others moderately affected, and some low at all.

iii. Drought

Drought is described as the unavailability of water due to extreme weather conditions such as long periods of abnormally low rainfall. It is also a condition of moisture deficit sufficient to have an effect on vegetation, animals, and man over a sizeable area. Basically, a drought-related hazard is an event in which a significant reduction of water brings about severe economic, social, and environmental hardships to the population.

Vulnerability to drought is the relationship of susceptibility to physical factors, exposure to climatic factors, and adaptability to anthropogenic factors. Basically, each factor can be assigned a relative weight according to its influence. Each factor, with the specific hazard values can be prepared and analyzed for simulation. All factors follow the same scaling factor procedures to assess and map out vulnerable areas. Overall, drought hazard maps for observed, 2020s and 2050s periods may be produced based on different factors and their relative weights. Different factors are described below:

Layer/ Factor	Classes/Ranges	Relative weights
SENSITIVITY		
Annual Rainfall	<800	1
	800 - 1200	2
	1200 - 1600	3
	1600 - 200	4
	>2000	5
Number of dry months (Alternate indicator)	1	1
	2	2
	3	3
	4	4
	>4	5
Number of dry days (dry spell/drought) (Alternate indicator)	<3 days	1
	4 – 6	2
	7 – 9	3
	10 - 12	4
	>12 days	5

Proximity within existing irrigation canals and rivers (buffer ranges in m)	0-250	1
	250-500	2
	500-1000	3
	2000-3000	4
	>3000	5
Types of rivers and streams	None	5
	Ephemeral	4
	Intermittent	3
	Semi-perennial	2
	Perennial	1
Number of hot days (max temperature with >35 °C)	<1 day	1
	1 – 7	2
	8 – 14	3
	15 – 21	4
	>21 days	5
EXPOSURE		
Population Density (person/ha) by barangays	<10	1
	10 - 50	2
	50 - 100	3
	100 - 500	4
	>500	5
Extent of production areas/SAFDZs over total land areas (%)	<10	1
	10 - 20	2
	20 - 30	3
	30 - 40	4
	>40	5
ADAPTIVE CAPACITY		
Availability of small – scale irrigation program	Available	1
	Partially available	3
	Not available	5
Water impounding or rain harvesting facilities	Available	1
	Partially available	3
	Not available	5
Maps of drought prone areas	Available	1
	Partially available	3
	Not available	5
Access to drought forecasting information and early warning system	Available	1
	Partially available	3
	Not available	5

Climate-related droughts given three different periods can be generated and labeled as high (yellow), moderate (grey), and low (green). The attribute table can be then generated to determine a barangay's exposure to drought. The spatial assessment indicates the total number of barangays that are highly vulnerable to drought.

d. Validation on the ground

Ground validation or ground-truth is one of the components of simulation and modeling. The product of simulation based on physical,

demographic, vegetative, and climate data can be validated on a given site. Basically, stakeholders within the areas (*i.e.*, various municipalities) who are familiar with the physical conditions are considered key informants. Each informant will be asked of his/her observation on the degree of hazard susceptibility for each barangay. Normally, highly susceptible barangays are considered to have previous experiences of landslides, droughts, or floods.

2. GIS for Land Use Decision-Making

a. *Defining the landscape*

A landscape may mean many things to a person depending on tradition and perhaps more validly, disciplinary bias. To a person schooled in landscape architecture and design, a landscape consists of people, softscapes, and hardscapes. Softscapes referring to the biological component – the people, plants, and animals that hold the landscape as their home and source of food. Hardscapes, referring to the built environment – the pavements, light posts, and other man-made structures built of metal, cement, wood, and other materials. To an engineer, a landscape or a site is something that you build on, be it a skyscraper, a pavilion, or as grand as holiday resort or as simple as a sitting bench (Bantayan *et al.*, 2000; Bantayan *et al.*, 2015).

b. *Land evaluation*

Land evaluation is a process whereby the potential of land for a particular use is estimated. It may be categorized as qualitative, quantitative, or economic evaluation. A qualitative evaluation is limited by its description of the landscape where land for alternative uses are expressed in terms of highly suitable, moderately suitable, or not suitable. Mabbutt (1968) discusses two types of qualitative evaluation: the generic and landscape approaches. The generic approach uses so-called natural regions based on climate, particularly precipitation. The landscape approach, on the other hand, is based on the analysis of the visible features of the area.

c. *Land classification*

Land classification becomes necessary when addressing continuously varying quantitative spatial properties, an issue typical to land use planning. Because data are usually closely related, it is easier to simplify these without sacrificing the results. An important first step in classification is to have a good working knowledge of the characteristics of the data set. This is to avoid classes that do not exhibit similar characteristics. According to Burrough (1989), a good classification system is one which takes up as much of the variation in the data set as possible. In addition to the homogeneity of the resulting class intervals, arbitrary decisions should be minimal in the designation of land classes.

The advantage of homogenous land units resulting from a land classification procedure allows the land to be allocated in a rational manner. The allocation of land units depends on the capability as well as suitability to a specific land use – which is a classification on land capability and land suitability.

d. Land capability classification

Land capability refers to the inherent capacity of land to support, on a sustained basis, a particular use or set of uses. One may look at land capability as the carrying capacity of the land in terms of the uses that may be allowed in an area without leading to the degradation of the land and the resources found therein. In effect, land capability sets the limit to which a particular use of the land can be carried out safely beyond which the sustainability of the land and other resources suffer serious jeopardy. It is generally determined by the biophysical attributes of the area.

The concept of land capability has been widely used in land use planning as a tool for ascertaining the uses that are most suited to an area without resulting to land resources degradation. Land capability evaluation, defined as the subdivision of large tracts of land into capability classes each consisting of biophysically homogenous areas with distinct ability to accommodate a set of uses (*i.e.*, forest protection, forest production, agro-forestry, agriculture, residential, commercial and industrial) on a sustainable basis, can be used in identifying the best development options for the project area. Specifically, the result of land capability classification is used to define the different land use zones in the municipality or project site in particular, and in the watershed in general.

e. Method of land capability classification

Land capability evaluation process looks at the characteristics of each factor and how it affects the land's capability to sustain the forest ecosystem. This process can be applied as a product of land capability classification, which is undertaken using the potential soil erosion of an area as basis.

Figure 3 shows the structure derived from the erosion-based land capability classification system (LCCS) developed by Warren *et al.* (1989) in the United States and applied by Cruz (1990) in Ibulao Watershed, by De Asis (1998) in UP Land Grant, Quezon-Laguna, by EDC (2012) in five (5) geothermal project sites, Department of Environment and Natural Resources (DENR)-Region 4 (2013) in San Juan River Watershed, and DENR-United States Agency for International Development (USAID) (2015) in four (4) B+WISER program sites.

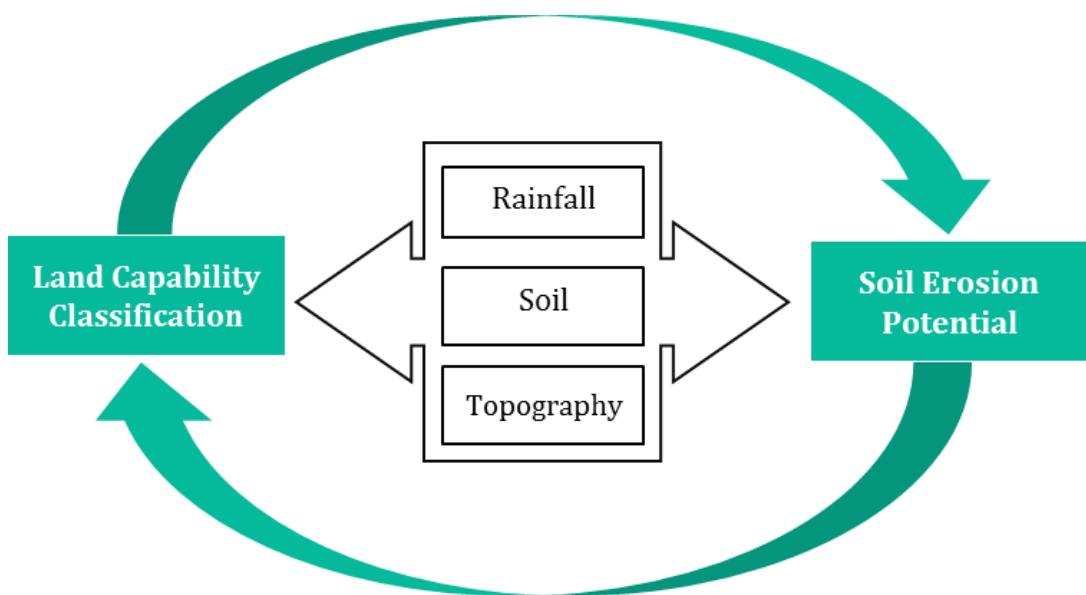

Figure 3. Erosion-based land capability classification associated with biophysical factors (CFSHD-DAP, 2015; USAID-DENR, 2015)

f. Land use modelling

Modelling soil erosion is the process of quantitatively describing soil particle detachment, transport, and deposition on land surfaces (Nearing, *et al.*, 1994). These models are useful tools for understanding the erosion process and the interactions of the factors affecting soil loss. From this information, appropriate measures can be taken to reduce the negative impacts and also prescribe proper land use management strategies.

Soil erosion is a suitable indicator of land capability because of common key determinants (*i.e.*, rainfall, soil, and topography). Soil erosion is also a good measure of the sustainability of land productivity, which is the primary success indicator of land capability. The premise of an erosion-based LCCS is that any use compatible with a specific land capability class (LCC) or zone will not cause significant soil erosion that leads to the deterioration of land productivity, soil, and water resources. Further, the planned use should not bring about adverse offsite impacts. Climate change-related hazards such as floods, rain-induced landslides, and other natural hazards impose limitations on the potential uses of LCC.

Following the procedures described by Warren *et al.* (1989) and with the aid of GIS analytical techniques, erosion index can be developed and used for land capability classification.

Generation of Soil Erosion Potential

Soil erosion potential (SEP) can be estimated given the relationship of rainfall (R), soil (K), slope (S), plant cover and farming techniques (C), and erosion control practices (P). SEP is computed using the equation below. The C will be excluded because it can easily be altered by human activities.

$$SEP = R \times K \times S$$

Creation of Soil Loss Tolerance

Soil loss tolerance limit is a common expression of the SEP estimates (Table 1). The T value is an expression of the maximum soil loss that an area can sustain without regressing in productivity permanently or temporarily. It is a function of the rate of soil accumulation in an area that is dependent on the slope of an area. Hence, the slope might be reclassified according to its soil loss tolerable limits.

Table 1. Prescribed soil loss tolerance

Slope	Soil Loss Tolerance (ton/ha)
0 – 3	12
3 – 8	10
8 – 18	8
18 – 30	6
30 – 50	4
>50	2

Determination of Soil Erosion Index

The computation of soil erosion index (SEI) is essential to standardize SEP estimates. As it is, the SEP per se when directly used as indicator of sensitivity or susceptibility of an area to soil erosion, does not capture the full weight of slope as a determinant of soil erosion in an area.

g. Land use allocation

Land use zones can be delineated based on land capability as indicated by soil erosion index, and other criteria as shown below (Table 2). Two (2) major zones, namely protection and production, are identified. Each major zone can be further classified into subzones. It is noted here that the output zonation and the indicative land uses in the area are intended to provide a scientific basis for allocating lands in the municipalities to various uses.

Table 2. Land capability classification criteria

Class	Land Classification	SEI	Considerations
I	PROTECTION AREAS		
IA	Strict Protection Zone	>3	All remaining natural forests; Areas with high erosion potential; Slope >50% All key biodiversity areas; All areas categorized as SAFDZ; All areas above 1,000 masl (DENR, 1991)
IB	Protection Buffer Zone		Banks of rivers and streams and the shores of the seas throughout

Class	Land Classification	SEI	Considerations
			their entire length and within a zone of 3 m in urban areas, 20 m in agricultural areas and 40 m in forest areas, along their margins (Section 17, Pres. Decree [PD] 705, and pursuant to the provisions of the Water Code)
II	PRODUCTION AREAS	0 - 3	
IIA	<i>Unlimited Production Zone</i>	0 - 1	Built-up areas; Slope less than 18%
IIB	<i>Multiple Use Zone</i>	1 - 2	Open brushland and grass land areas; Slope less than 18%
IIC	<i>Limited Production Zone</i>	2 - 3	Slope less than 18%

A GIS analysis generates management zones, namely: strict protection zone, restoration zone, buffer zone, limited production zone, multiple-use zone, and unlimited production zone. Management prescriptions of the land capability classes are the following:

Protection Areas

Protection areas are designated mainly for the conservation of biodiversity; conservation of soil and water; protection of unique habitats, vegetation, geologic formation and landscape, and areas of sociocultural values; and minimization of climate-related and other natural risks and hazards associated with soil erosion, landslides, and floods.

Strict Protection Zone

Strict Protection Zone, as defined in Section 5.23, DENR Administrative Order (AO) 2008-26, pertains to management zones of protected areas consisting of natural areas with high biodiversity value closed to all human activities except for scientific studies and/or ceremonial or religious use. It may include habitats of threatened species, or degraded areas that have been designated for restoration and subsequent protection, even if these areas are still in various stages of regeneration.

Stream Buffer Zone

The banks of rivers and streams, and the shores of the seas throughout their entire length and within a zone of 3 m in urban areas, 20 m in agricultural areas, and 40 m in forest areas, along their margins, are subject to easement of public use in the interest of recreation, navigation, float age, fishing and salvage. This provision is mandated by law (Section 17, PD 705) and pursuant to the provisions of the Water Code. These areas are essential buffers for rivers that serve as filters to incoming sediments and other

pollutants. These buffers that are supposed to be covered with vegetation, are also excellent protection of the streamflow against excessive solar exposure to keep water temperature at ideal level.

Production areas

The production zone is made up of lands that are suited for intensive land uses such as farming, multiple use forestry, and other uses requiring disturbance of the soil and other resources found in the area. This zone also includes areas that are used for settlement and urbanization and other built up purposes.

Multiple Use Zone

Multiple use zone, as defined in Section 5.10 of DENR AO 2008-26, pertains to the management zone of protected areas where settlement, traditional and/or sustainable land-use including agriculture, agro-forestry, and other income-generating or livelihood activities may be allowed consistent with the Management Plan. It also includes, among others, areas of high recreational tourism, educational or environmental awareness values, and areas with existing installations of national significance or interest such as facilities or structures for renewable energy, telecommunication, and hydro-electric power generation, among others. However, the land capability classification of the multiple use zone is placed under production areas since it requires intensive management requiring soil disturbances.

Limited Production Zone

Limited production zones can be allocated as agricultural areas that are classified within the alienable and disposable lands.

Unlimited Production Zone

Areas for settlement and commercial purposes consist mostly of areas that are currently used for the same purposes. As the town's population continuously grows, the settlement and community areas may expand only to production areas immediately adjacent to existing areas. By no means, the areas for settlement and community purposes should be permitted to extend in multiple use, even in the protection areas, as this will likely compromise ecological and environmental integrity.

3. GIS for Local Governance

a. Integrating GIS in Natural Resource Organizations

In the Philippine context, local government units are the most potent instruments for sustainable forest and natural resources management. Several reasons point to this observation:

- LGUs are at the 'frontline,' owing to their presence in all areas of the country especially where forest destruction occurs;

- LGUs have jurisdiction over upland dwellers, especially those at the boundary of forestlands and private lands (*i.e.*, ‘forestline’), where conversion and resource extraction is apparent;
- LGUs are the most potent entities that can sustain efforts at protecting and restoring forests and natural resources. Compared to other government agencies with similar concerns, LGUs have the ‘home advantage.’

For a natural resource manager, having a GIS unit to handle the spatial databank of the organization is desirable. In most cases however, GIS activities are ad hoc, and once the GIS has been plotted and printed, the GIS unit ceases to exist. More often than not, these activities are contracted out to GIS companies. Thus, the use of GIS must be institutionalized within the organization and not just an ad hoc activity.

b. Community-based GIS

Community-based GIS can be seen in terms of utilizing GIS technology in enhancing the capability of upland communities to better manage natural resources around them. The process consists the following:

1. Preparation and plotting of the GIS themes.
2. Conduct of an appreciation workshop on participatory mapping using GIS and 3D relief modelling.
3. Construction of the 3D relief model per barangay.
4. Transferring of ‘mental maps’ onto the 3D model.
5. Ground verification.
6. Updating of the land use on the 3D relief model.

c. Poverty Mapping

Poverty stems from the lack of access to resources and opportunities that would enable a human to achieve a level of well-being. Thus, lightly defined, poverty is the ability (or inability) to attain a minimal standard of living. This minimum level is usually called the ‘poverty line.’

Integrating GIS in mapping poverty, therefore, is a necessary task. A poverty map is a geographic profile indicating concentrations of well-being. Such maps are useful, for instance, in targeting interventions and policies geared towards alleviating poverty.

For instance, GIS-assisted poverty mapping, may be implemented based on the following:

- Accessibility to resources and services
- Biogeographical mapping
- Vulnerability mapping

d. LGU and Land Use Planning

The concept and interpretation of the comprehensive land use plan as embracing the entire LGU territorial jurisdiction derive from the reality that in any LGU territory there exists two, possibly three, property domains: private, public, and ancestral.

- The private domain includes areas that had earlier been classified as alienable and disposable, and have since been titled to private owners or claimants. The private domain is completely under the authority of an LGU to regulate.
- Public domain lands such as forests, national parks and similar reservations, which are within the territorial limits of an LGU are traditionally the preserve of the national government. LGUs usually do not have anything to do with those areas. But now, the national government intends to involve LGUs in the management of these areas and resources.
- Another domain that may be present within the territory of an LGU is the ancestral domain. The Indigenous People's Rights Act (RA 8371) declares these areas as exclusively for the use and occupancy of the particular ethnic and cultural group that had occupied the area since time long-established.

Management plans of ancestral domains/lands, nevertheless, shall be integrated into the Comprehensive Land Use Plan of the LGU having territorial jurisdiction.

Through GIS technology, intervention options or management prescriptions may be developed on the basis of the major strategies: protection, production, and intensive use. GIS can be used to assist the community transform their mental maps into tangible forms that can allow georeferencing and spatial analysis. GIS can help communities plan out the most appropriate farming system (*i.e.*, agroforestry) design. Implementation may be done by visualizing the land-use location and allocation problem as a set of map layers or themes representing earth features. Generating thematic layers allows for selective combination that answers specific questions. Thus, GIS technology has allowed many LGUs to better manage their activities as well as identify solutions to pressing problems in a more responsive way.

4. Land Change Modelling

a. *Change analysis*

Changes can be tracked and described in terms of trends, rate of change, persistence, and nature of change. Using land change modelling, users are allowed to specify the essential files associated with the land cover change analysis of a specific area, as well as a project name. For the change and prediction analyses, a minimum requirement is the specification of two land cover maps that can be used as the basis for understanding the nature of change and the means of establishing samples of transitions that should be modelled. The two land cover maps must have matching backgrounds, legends, and spatial characteristics.

Changes in land use and land cover detected through GIS analysis can be validated through limited ground verification surveys and interviews with key informants and members of local communities.

b. Transition analysis

Two main types of forest change are of interest in the land use change analysis: forest to non-forest (forest loss) and non-forest to forest (forest gain). Forest loss (deforestation) is defined as the direct human-induced conversion of forested land to non-forested land or more specifically, as the conversion of forest to other land use or the long-term reduction of tree canopy cover below the minimum 10% threshold (Food and Agriculture Organization [FAO], 2010). Deforestation falls under the category on forestlands converted to other land uses based on the IPCC Good Practice Guidance on Land Use, Land Use Change, and Forestry (LULUCF). Other land uses as defined in this same framework include the following broad land use/cover categories, particularly: cropland, grassland, wetlands, settlements, and other land.

On the other hand, forest gain (forestation) is defined as non-forestlands converted to forestlands and is reflected in new forests being established (i.e., afforestation and reforestation). According to the IPCC Good Practice Guidance on LULUCF, “afforestation” is the direct human-induced conversion of land that has not been forested for a period of at least 50 years to forested land through planting, seeding and/or human-induced promotion of natural seed sources. On the other hand, “reforestation” is the direct human-induced conversion of non-forested land to forested land through planting, seeding and/or human-induced promotion of natural seed sources, on land that is forested but has been converted to non-forested land.

For instance, land cover assessment can be utilized (2003 and 2010 land cover data produced by the National Mapping and Resource Information Authority [NAMRIA]) for generating activity data and analyzing forest cover change. Both the 2003 and 2010 land cover data can be generated using visual interpretation and manual editing from 30m-resolution Landsat data categorized into FAO land use classes, which consist of: nine (9) forest classes, two (2) agricultural classes, three (3) wetland classes, four (4) grassland classes, and two (2) other-land classes.
